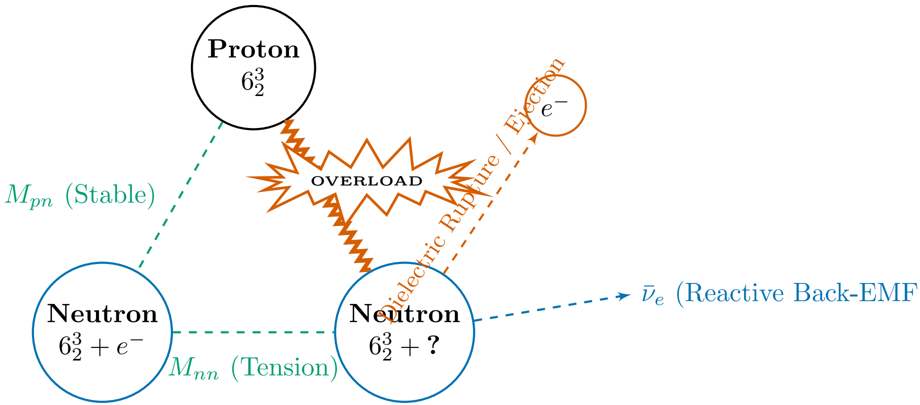
Tritium (β^--Decay Transient Failure)



Tritium Beta-Minus (^{3}H $\rightarrow^3$ He + e^- + $\bar{\nu}_e$)

The geometric asymmetry of 1 Proton + 2 Neutrons creates an unstable LC loop. Capacitive tension in the overarching node cluster exceeds the structural V_{yield} limit. The secondary electron topology stored within the Neutron node—a 0_1 unknot body carrying the $(2, 3)$ Clifford-torus winding in *phase space* (the 3_1 trefoil is that phase-space portrait, not a real-space body knot)—is ejected as transient energy dissipation, converting the node to a stable Proton.
